(54) Title: ITINERARY BASED AGENT MOBILITY INCLUDING MOBILITY OF EXECUTABLE CODE

#### (57) Abstract

In accordance with the present invention, a mobile agent object (10) executes a first method (18) on a first computer (12), migrates from the first computer (12) to a second computer (14), and executes a second method (20) on the second computer (14). The first and second methods and first and second computers are designated in an itinerary (28). The agent includes both data (22) and executable code (24, 26) which are serialized for transmission from the first computer to the second computer as data. The data containing the agent is then descrialized in the second computer to regenerate the agent in the form of an object. The executable code portion of the agent can be supplemented with code from a home codebase located on another computer.

#### CROSS REFERENCE TO RELATED APPLICATIONS

A claim of priority is made to U.S. provisional patent application Serial Number 60/030,906, entitled USE AND COLLABORATION OF MOBILE AGENTS IN A COMPUTER NETWORK, filed November 14, 1996.

# STATEMENT REGARDING FEDERALLY SPONSORED RESEARCH OR DEVELOPMENT Not applicable

### BACKGROUND OF THE INVENTION

The present invention is generally related to network computing, and more particularly to mobile objects.

Mobile objects that are transmitted across a computer network are known. Mobile objects are comprised of code and data, both of which are transmitted across the computer network. Technologies such as client-server protocols, remote procedure call protocols, and distributed object technologies are employed to transmit mobile objects across the computer network. These technologies implement either a "push" model or a "pull" model, both of which have drawbacks.

In a "pull" model the code for an executing object is downloaded from a network source such as a web server. When a particular portion of code becomes necessary for operation, that portion of code is first sought on the local filesystem. If the local filesystem does not include that portion of the code, a network request is sent to another computer in the network in order to prompt transmission of that portion of code to the local computer. However, as different classes of sub-objects are created, a separate network request must

be sent to retrieve code for each class. In the case of a Hyper-Text Transfer Protocol ("HTTP") request, each request must re-establish a Transmission Control Protocol/Internet Protocol ("TCP/IP") socket connection to the web server. Thus, when downloading a large number of classes, a large number of connections must be established and a large amount of network overhead is incurred.

5

10

15

20

25

30

35

Another drawback associated with the pull model is that as an object travels, the code which enables the object to operate must be re-downloaded at each computer. More particularly, when the object arrives at each a destination computer, the object downloads any code which is required but not present on the local filesystem, even if that code was downloaded at the previous destination computer. Previously downloaded code is not cached. Network overhead is incurred as a consequence.

In a "push" model the code for an executing object is carried with the mobile object. Prior to launching the mobile object, all of the code that will be needed by the object is identified. The code is packaged with the agent and pushed around the network to each destination computer. While the push model reduces network requests in comparison with the pull model, network overhead is still incurred because of the relatively large amount of code that is pushed to every destination computer. In some cases the object will push code for classes that are no longer needed. For example, an agent may create an instance of a particular class of object only in very exceptional circumstances. In such a case it is inefficient for the object to push the code for this class.

Another limitation of known mobile objects is difficulty in examining and predicting destination information. Known mobile objects initiate travel by performing a subroutine call. The method is sometimes given a name such as "go" or "moveTo," and the caller is responsible for specifying a name or Uniform Resource Locator ("URL") indicating the destination computer for the mobile object. When the travel method is called, the execution of the mobile object is

-3-

halted and the mobile object is converted into a network transmittable form. On the destination computer the mobile object is restored from the network form and restarted. This restart can either occur on the instruction directly following the call to the travel method, or at the beginning of some known method.

codebase.

#### BRIEF SUMMARY OF THE INVENTION

In order to provide efficient mobility of code for a mobile agent object ("agent"), a "mobile codebase" object is constructed. The mobile codebase travels with the agent and serves as a repository of code for classes that facilitate agent operation. When the agent is launched, the launcher specifies a list of related classes. These classes are retained in the mobile codebase. The launcher also specifies a Uniform Resource Locator ("URL") that points to a network source ("home codebase") from which code can be downloaded. If the agent is required to instantiate an object comprising code that is not in the mobile codebase, a network request is sent to the home codebase to retrieve that code. Code that is downloaded in this manner is retained in the mobile

The combination of the mobile codebase and home codebase improve agent operation and reduce network overhead. In a preferred embodiment an agent is launched with a mobile codebase that is preloaded with classes which are certain to be needed. Classes that are unlikely to be needed are stored in the home codebase. Thus the agent with mobile codebase and home codebase provide the desirable features of the push and pull models without the undesirable network overhead incurred by transmitting unneeded classes around the network or re-downloading code.

Agent travels are defined by an itinerary data structure. The itinerary is composed of a list of destinations, each of which includes: (1) the hostname of a destination computer on the network to which the agent should travel, and (2) the name of a method that the agent should

-4-

execute when the agent arrives at the destination computer. An agent is allowed to modify its itinerary. When an agent modifies its itinerary, the agent owner is automatically notified, thus allowing the owner to "follow" the agent wherever it may travel.

The itinerary provides advantages related to agent and network management. Inspection of the agent itinerary reveals where the agent has travelled and where the agent may travel in the future. Since the itinerary is a standard data structure, an observer can depend on it to be present. Further, since the itinerary is a separate data structure from the agent, the observer does not need special knowledge of the internal structure of the agent in order to examine the itinerary.

#### BRIEF DESCRIPTION OF THE DRAWING

The invention will be more fully understood from the following Detailed Description of the Invention, in conjunction with the Drawing, of which:

Fig. 1 is a block diagram which illustrates agent migration;

Fig. 2 is a block diagram which illustrates agent execution in conjunction with agent migration;

Fig. 3 is a block diagram of an agent;

Fig. 4 is a block diagram of agent interaction with agent managers on multiple computers in a network;

Fig. 5 is a flow chart which illustrates agent mobility;

Fig. 6 is a block diagram which illustrates agent operation according to an itinerary;

Fig. 7 is a block diagram which illustrates the agent runtime environment; and

Fig. 8 is a flow chart which illustrates agent descrialization.

35

DETAILED DESCRIPTION OF THE INVENTION

Referring to Fig. 1, an agent 10 comprises a mobile

-5-

object which can travel from a first computer 12 to a second computer 14 in a computer network 16. The agent is generated and stored in memory on the first computer for a specific purpose, and includes both data and executable code. The agent executes on the first computer and then migrates to the second computer by being transmitted across the network. The agent then resumes execution on the second computer. When the agent completes execution on the second computer, the agent acts in accordance with an agent itinerary. For example, the agent will migrate to another computer if the itinerary so indicates.

5

10

15

20

25

30

35

Referring now to Figs. 1 and 2, the agent executes a sequence of instructions during operation. In particular, a first method 18 is executed on the first computer 12 and a second method 20 is executed on the second computer 14. As a result, migration between computers is transparent from the perspective of the agent.

Referring to Fig. 4, agent mobility is preferably facilitated through use of JAVA agent manager Objects 32 and Object Serialization facility (a product of art). Microsystems which is known in the Serialization operates to serialize objects such that a representative stream of bytes, i.e., data, is generated therefrom. Object Serialization facilitates transmission of an agent across the network by serializing the agent 10 into a format that is suitable for network transmission. Serialization of the agent may also include serialization of sub-objects which are contained within member variables of the agent. In accordance with the present invention, the involves the serialization of serialization process executable code, data, and an itinerary as hereinafter discussed in greater detail. Once the agent has been serialized, a communication socket to the second computer is opened and the resulting stream of bytes is transmitted to the second computer along the socket.

The serialized agent is regenerated in the second computer 14 upon arrival. In particular, the stream of bytes transmitted along the socket is deserialized in the second

-6-

computer. Deserialization regenerates the agent in the form in which the agent existed prior to migration, i.e., an Following deserialization, the agent executes a predetermined method specified by its itinerary. predetermined method may prompt interaction with another object 34 located on the second computer. When the method has been executed, the agent is serialized and transmitted to yet another computer, or possibly back to the first computer. The agent is therein deserialized upon arrival and proceeds to execute another predetermined method and interact with that computer. In the case of the agent migrating back to the first computer, such interaction could be with a host application 36 through which an information query was The agent continues migrating across the network in this manner as execution requires. Eventually, the agent is terminated when execution of the itinerary is complete. It should be noted that the agent need not necessarily migrate to the initial host (first) computer after executing on a remote (second) computer. The agent could travel to multiple computers, and may not return to the initial host computer.

5

10

15

20

25

30

35

Referring to Fig. 3, each agent may include data 22, code 24, sub-objects 26 and an itinerary 28. The data portion 22 includes internal state information associated with the agent. The code portion 24 includes executable code associated with operation of the agent. The itinerary portion 28 specifies destinations for the agent. Sub-objects 26 include code of distinct objects contained within the agent. The agent carries the code for these sub-objects.

The code 24 portion of the agent 10 includes a mobile codebase and a reference pointer to a home codebase. The mobile codebase comprises executable code which is retained as part of the agent. When the agent migrates, the mobile codebase is transmitted along with the data, sub-objects and itinerary to the destination. The home codebase is executable code which resides on the computer which originally created and launched the agent or a suitable network server (such as a web server). The reference pointer

-7-

to the home codebase is a Uniform Resource Locator ("URL") that allows remote access to the home codebase from other computers in the network. If the agent requires code that is not present in the mobile codebase during execution, the agent retrieves the required code from the home codebase and retains such retrieved code in the mobile codebase.

Referring to Figs. 3 and 6, the itinerary 28 is a data structure which defines agent migration parameters. The itinerary is composed of a list of destinations and the name of a method associated with each such destination. In a preferred embodiment, each destination entry contains the Transmission Control Protocol/Internet Protocol ("TCP/IP") host name of a computer on the network to which the agent is designated to migrate. The method associated with the respective destination is invoked upon arrival at that destination. Hence, each destination represents a location and a task to be performed at the location.

Figs. 4 and 5 illustrate agent mobility. When the determination is made that the agent should migrate, the agent manager 30 examines the itinerary 28 to ascertain the next destination to which the agent 10 is designated to migrate. The agent manager 30 establishes a network connection to the agent manager 32 at the destination computer 14. The agent manager 30 passes the agent and related travel information to the destination agent manager 32. The agent manager 30 then deletes the local copy of the agent, terminates any execution threads which were being used by the agent, and performs other appropriate clean up activities.

From the perspective of the destination computer, the agent arrives at the destination computer as illustrated in step 38. As previously described, the agent arrives in the form of data which includes the code, sub-objects, itinerary and other data. Java/Object Serialization assists the describination and reconstruction of the agent as depicted in step 40. The server then spawns a new thread in which the agent will execute as shown in step 42. A persistent local copy of the agent is then made as illustrated in step 44.

30

5

10

15

20

25

35

As depicted in step 46 the agent manager invokes the proper method of the agent for execution in the spawned thread at this node. The itinerary contains information indicating which method should be invoked at each designated destination computer. The agent then executes as illustrated in step 50.

5

10

15

20

25

30

35

When the agent has completed execution of the indicated method, another persistent copy of the agent is stored on the local disk as depicted in step 52 in order to prevent redundant execution in the event that the The agent manager malfunctions before the agent migrates. then examines the agent itinerary as illustrated in decision If the itinerary does not indicate any further destinations then agent execution is deemed complete as shown However, if the itinerary indicates further in step 56. destinations, then the agent manager determines whether the next destination is associated with another computer in decision step 58. If the next destination is not another computer, flow returns to step 44, thereby bypassing network traffic. However, if the next destination is associated with a different agent manager then a network connection to the indicated agent manager is established as depicted in step 60. The destination contains a string which indicates where to travel. The string contains either the name (host name) of a computer or a URL to a distributed object. is then serialized as illustrated in Step 62 and subsequently transmitted to the next agent manager as depicted in Step 64.

Migration in accordance with the itinerary 28 is further illustrated in Fig. 6. The itinerary includes a listing including identification of each agent manager 66 to which the agent is configured to migrate and identification of a method 68 to execute at each respective agent manager. The agent migrates through the agent managers listed in the itinerary sequentially in the order in which the servers are listed, invoking each respective method upon arrival. Such method could be, for example, querying or updating a database on the destination computer.

Fig. 7 illustrates the agent runtime environment. Each

-9-

computer 70 on the network includes a Java Virtual Machine 72 running therein. A agent manager 74 runs on each respective Virtual Machine 72. The agent manager includes a plurality of threads 76, each thread having an agent 78 associated therewith. In particular, a new thread is formed when a new agent arrives at the server, and the agent executes on that thread. Security mechanisms prevent each agent from operating outside the scope of the associated thread. When agent execution completes, the agent migrates to the next destination identified in the itinerary.

In order for migration and execution to function properly, the agent manager modifies the mechanism by which Java loads classes. The Java standard library provides an object called a "ClassLoader" which can be subclassed by a programmer to modify the rules that Java follows to load classes. The ClassLoader class allows web browsers to download "applets" from a web server. The agent manager provides a specialized ClassLoader which allows the executable code for mobile agents to travel with the agent.

During a typical execution of a Java program, a Java interpreter loads classes as needed for execution from a logical file system on the local computer. However, agents become separated from the home computer and the home codebase during migration, i.e., agents are separated from the directory or directories on the filesystem of the home computer where the code is stored. Further, sub-objects sometimes need to be created as the agent executes, either as member variables or as temporary variables within the These sub-objects could be instances of classes which are part of the standard Java packages or they could be instances of new classes written by the programmer of the agent. However, since the agent is executing on a different computer than the home computer following migration, the Java virtual machine may not be able to directly retrieve the code for the particular sub-object. To allow agents to properly load classes and construct objects when remote from the home computer, a special ClassLoader is employed by the agent manager whenever an agent attempts to construct an object.

15

5

10

20

25

3.0

35

-10-

The ClassLoader object first attempts to locate a class on the local file system of the computer. If the class is not on the local file system, the ClassLoader searches the mobile codebase. If such attempt fails, the ClassLoader sends a request back to the home machine of the agent. The agent's travel information contains a reference such as a URL which refers back to the home codebase on the home computer, and by accessing the URL the ClassLoader can retrieve classes from the home computer.

10

15

5

Agent descrialization is illustrated in Fig. 8. As depicted in step 80 the scrialized agent arrives as a stream of data. Java Development Kit Object Scrialization classes then call an agent manager related method to perform descrialization as shown in step 82. The method reads agent related objects from the object stream as depicted in step 84. In particular, the mobile codebase, itinerary and codebase URL are read by the method. A custom Classloader and ObjectInputStream are constructed as shown in step 86. Object Scrialization then reads the agent and other objects from the input stream as depicted in step 88 and step 90, respectively. When the related objects are read, the ClassLoader retrieves the classes which comprise the agent as illustrated in step 92.

20

25

30

35

The new object's class is loaded once the classes are As depicted in step 94, if the class is retrieved. determined to have been previously loaded then the previously loaded class instance is employed (step 96) and the object is instantiated using the loaded class object as shown in However, if the class has not been previously loaded as determined in inquiry step 94, then inquiry is made as to whether the class is on the local class path of the destination computer as illustrated in decision step 100. If the class is present on the local machine then the class is loaded therefrom as shown in step 102 and the object is instantiated using the loaded class object as depicted in step 98. However, if the class is not found on a local class path as shown in step 100 then an inquiry is made as to whether the class is in the mobile codebase as shown in step

-11-

104. If the class is located in the mobile codebase then the class is loaded therefrom as shown in step 106 and the object is instantiated using the loaded class object as shown in step 98. However, if the class is not located in the mobile codebase in decision step 104 then the class is loaded by accessing the home codebase as shown in step 108. If the codebase pointer is an Internet type pointer such as a Hyper-Text Transfer Protocol ("HTTP") URL, as determined in inquiry step 110, then an HTTP request is sent to the local web server as shown in step 112 and the retrieved class is added to the Mobile CodeBase as depicted in step 114. However, if the codebase URL is not a HTTP URL then a remote method request is sent to a RemoteClassLoader object as shown in step 116 and the class is added to the mobile codebase as In either case, the object shown in step 114. instantiated using the loaded class object as shown in step 98. If more objects exist in the stream to be retrieved, as determined in decision step 118, then another object is read from the input stream as illustrated in step 90. If there are no more objects to be retrieved, flow terminates.

Having described the preferred embodiments of the invention, other embodiments which incorporate concepts of the invention will now become apparent to one of skill in the art. Therefore, the invention should not be viewed as limited to the disclosed embodiments but rather should be viewed as limited only by the spirit and scope of the appended claims.

A program listing follows in the attached APPENDIX.

collaborate with a specific Agent regarding a certain subject is not known a priori, but is, rather, determined as a result of the Agent's computations.)

Both the interaction between these Agents and the context in which they execute must be formally specified. Standardization has not yet been achieved for these objectives. However, the prevalent means for accomplishing these results is via implementing a user model and specifying queries and assertions by using a knowledge representation language, the most popular of which is currently Knowledge Query Manipulation Language (KQML), and by developing Ontologies, or vocabularies of common terms to be utilized by interacting Agents. KQML is comprised of both a language, with a syntax unlike procedural or object-oriented languages, and a communications protocol. An Ontology is defined as "an explicit specification of a conceptualization". The syntax and semantics of an Ontology are generally extensions of a first-order predicate calculus, typically the Knowledge Interface Format (KIF).

The combination of KQML, KIF, and Ontology development is a complex task. Some implementations utilizing these mechanisms are being developed in the Artificial Intelligence community. But this approach has not caught on in other software applications.

In contrast to Intelligent Agents, Mobile Agents are usually explicitly programmed to accomplish a specific task. As an example, a Mobile Agent could migrate to travel agencies on the World Wide Web and determine the lowest cost air fare between two cities. In this case, there is no need for learned behavior or complex reasoning.

However, the amount of information accessible on distributed systems, including databases, the Internet and Intranets, is growing at a staggering pace and much of it is available in incompatible storage formats. The need to filter information and make decisions based on its content is increasing, and with it, the need for increased collaboration among Mobile Agents.

The need for collaboration is illustrated by extending the above travel agency example. A Mobile Agent may need to clone itself and instruct each of its counterparts to migrate to a different travel agency site to obtain the best package for a trip to one or more ski resorts meeting certain parameters, including air fare, ledging, meets, lift tickets, and car rental Furthermore, the information may, itself, be sorted in different formats (databases, etc.), necessitating some amount of filtering and data reformatting. Once the Agents have obtained their information, they need to collaborate with each other to correlate their results and determine the best package available at each resort for different travel dates and the overall best deal.

Mobile Agents are evolving to include increased intelligence and collaboration. Some research organizations have begun incorporating KQML and Ontologies into Mobile

Agent implementations, while other utilize different knowledge representation languages to implement Agent communication. Still, others use proprietary object languages.

### 3. Problems with Prior Art

The KQML/Ontology mechanism and other knowledge representation languages are ill-suited for general-purpose software applications. They require programmers to learn multiple languages to formally specify communications and to develop complex dictionaries of terms—a task that is currently ill-defined. The knowledge representation languages are also extremely unlike the procedural and object-oriented languages utilized in building business and general-purpose software applications.

The need to support asynchronous collaboration adds significant complexity to Agent systems implemented via knowledge representation languages (e.g. KQML) and Ontologies. Furthermore, there exists a class of Mobile Agents which solely require synchronous collaboration, e.g., the travel agency application described above. This type of Agent application essentially subdivides a larger task into smaller pieces and creates Agents to migrate throughout the network to accomplish it. For these Agents, there is no benefit in the added complexity of coding in multiple languages and developing Ontologies, nor in the support for asynchronous communication. A synchronous collaboration framework in the Agent's language is the best means for these Agents to coordinate their results and implement adaptive behavior.

### 4. Some Details of the Invention

The dynamic synchronous collaboration framework utilizes a distributed synchronization point plus object-oriented abstractions to provide synchronous collaboration for Mobile Agents in a distributed system. The framework simplifies collaboration for applications which subdivide a complex problem into several pieces and farm out the work to multiple Mobile Agents.

This framework enables Mobile Agents within an application to perform synchronous collaboration with one or more affiliated Agents in the application's native language. This is accomplished via the Agent Group abstraction. Agents wishing to collaborate with each other must belong to one (or more) of the same Agent Groups. The fundamental principle behind Agent Group collaboration is that Mobile Agents performing sub-computations, possibly on different nodes in a distributed system, will need to periodically correlate their results, and potentially adapt their behavior based on the results of the correlation. The Agent Group acts as a distributed synchronization point for this type of synchronous collaboration.

### 1. Introduction

This document serves as a patent disclosure on the invention entitled Dynamic Synchronous Collaboration Framework for Mobile Agents. This document includes a discussion of: prior art, problems with prior art, details of the invention, and improvements of this invention over prior art.

### 2. Prior Art

"Agent" is one of the most overused terms in the software industry today. Although the term may be used in a wide variety of contexts, software Agents can be classified into two major categories: Intelligent Agents and Mobile Agents. Although the two differ in scope and capabilities, both types of Agents are able to perform work asynchronously and autonomously on behalf of their owners. Intelligent Agents are endowed with some degree of reasoning and learned behavior and may make decisions on behalf of their owners. These Agents are generally stationary and execute on a single system. Mobile Agents, on the other hand, may be transported across nodes in a network, performing computations as they migrate.

The original concept for Agents stems from the Artificial Intelligence community. The behavior of Intelligent Agents may be determined by programming or by decisions made by the Agents on behalf of their owners. As an example, an Intelligent Agent may search a database for unusual outdoor scenery, making its own decisions as to whether or not each scene meets the specified criteria.

Intelligent Agents generally employ both synchronous and asynchronous modes of communication. Agent communication may take the form of queries or collaborative computations. In the realm of Agent computing collaboration may be defined as "the coordination of the computations of multiple Agents to achieve a desired result" (e.g., to solve a complex problem). Collaboration often results from discovery (i.e. the need to

# Patent Disclosure for Dynamic Synchronous Collaboration Framework for Mobile Agents

November 12, 1996

Horizon Systems Laboratory Mitsubishi Electric ITA 1432 Main Street Waltham, MA 02154

The dynamic nature of the Agent Group enables Agents to join and leave the group at will. Hence no a priori knowledge of the actual Agents comprising a group is required and group membership may change over time.

A distributed name space maintains a reference to each Agent Group. Hence, Agent Groups may be located via their entry the name space. When an Agent Group is created, it is automatically added to the name space.

The Agent Group's primary responsibility is to facilitate synchronous collaboration for Mobile Agents. However, it also serves as a central point for distributing asynchronous events to Agents in the group. A typical event may be the termination of a particular Agent. As a side effect, the Agent Group also tracks the travels of its constituent Agents throughout the network.

The travel agency example illustrates the function of Agent Groups. The problem to be solved can be stated as follows: A user wishes to determine the best package for a trip to a ski resort. The Agents must determine the best travel date and time (e.g. any week in February starting on a Saturday, and Hying before noon) and lodging must meet certain criteria (e.g., a two-bedroom condominium). The trip includes all expenses (e.g., air fare, lodging, meals, transportation, and lift tickets). The user may also specify several possible travel destinations.

This application is composed of multiple Agents — each is responsible for querying one or more data sources (in perhaps different formats) for specific information (e.g., searching a particular travel agency's database of promotional trips to determine if any meet the criteria specified by the user.) Some Agents may query legacy database systems, whereas others may search ODBC compliant databases. (The actual mechanisms for handling different data sources is beyond the scope of this invention.)

Before the Agents are transported throughout the network they join a new Agent Group. The Agent Group tracks its Agents' travels throughout the network. At any point, an Agent may be in one of several states. Figure 1 depicts three Agents in an Agent Group performing computations and one Agent in-transit between nodes.

At different points during their migration. Agents may wish to correlate their results, and potentially change their migration plans or behavior. Suppose each Agent migrates to a local travel agency. Before migrating to travel agencies in different cities, the Agents may wish to correlate their results and potentially adjust their behavior. Suppose one of the Agents determines that a particular ski resort, say Taos, has no two-bedroom condominiums available during February. The Agents in the group may wish to drop all further queries about trips to Taos.

Agent Group collaboration is implemented via a distributed synchronization point (also known as a collaboration point) and a software routine to analyze the results of each

Agent's computation. The Agent Group abstraction provides the distributed synchronization point. Each application need only provide its own software method to analyze the results and potentially allow each Agent to adapt its behavior.

The distributed synchronization scheme requires that each Agent arrive at the collaboration point before collaboration may commence. Hence, it is best suited to applications that subdivide a complex problem into many sub-tasks that need to correlate their results. As each Agent arrives at the collaboration point, it posts the results of its computations to the Agent Group, and blocks until all the other Agents in the group arrive. Figure 2 depicts one Agent in the group waiting to collaborate while three others are still performing computations.

The Agent Group collects the results of each Agent's sub-computation. When all Agents have arrived at the collaboration point, as shown in Figure 3, the Agent Group notifies them that collaboration may commence. When it unblocks the waiting Agents, the Agent Group passes the collected results to each Agent. Each Agent then calls the application-specific method to analyze the results and potentially adapt its behavior. Figure 4 shows that all Agents have arrived at the collaboration point and are now in the analysis stage.

The synchronous collaboration framework supports both parallel and serialized collaboration analysis. Figure 4 depicts a parallel analysis implementation; Figure 5 illustrates a serialized collaboration analysis, in which one Agent is in the Analysis state, while the rest remain waiting in the Collaborate state.

The distributed collaboration point may be implemented via an object transport or by an RPC mechanism. It may also be implemented in any procedural or object-oriented language. Object-oriented languages simplify the implementation, as the application need only subclass the Agent Group abstraction and provide a concrete method to analyze the results and potentially adapt the Agent's future behavior.

The Agent Group ensures that all Agents in the group arrive at the synchronization point by tracking the Agent's migration through the network. In the current implementation, as part of a mobile Agent system, a server (known as the Conduit Server) on each node manages the Agent's migration and informs each of its Agent Groups when the Agent arrives and departs. Should an Agent fail to arrive at a collaboration point in a predetermined, configurable length of time, the Agent Group will "ping" the Agent by sending a message to ensure that it is still alive, as shown in Figure 6. (In the current implementation, this is performed via the Conduit Server on the node where the Agent is executing.) If the Agent fails to respond to the ping, the Agent Group notifies the other members of the group by distributing a Collaboration Failed asynchronous event to them that indicates that a particular Agent is not responding. The Agents may then indicate whether or not they wish to proceed with the collaboration. Figure 7 depicts the Agent Group's distribution of a Collaboration Failed event followed by the remaining Agents

indicating that they wish to continue the collaboration. Alternatively, the Agents could decide to abort the collaboration.

The Agent Group also implements deadlock detection by means of the time-out mechanism and Agent ping described above. The ping actually returns the state of the Agent in question (via the Conduit Server). If the Agent is already in the Collaborate state but has not arrived at this collaboration point, a deadlock has occurred. This is shown in Figure 8. In this case, the Agent Group will abort the collaboration and notify the Agents in the group of the deadlock by sending them a Deadlock Event, as shown in Figure 9. Note that since Agent Group collaboration is designed for closely coordinated Agents, the existence of a deadlock is generally a result of a programming error. Hence, the Agent Group does not need to employ a more sophisticated scheme for deadlock detection or avoidance.

Agent Groups provide reliability by saving the state of each Agent in the group to persistent storage. If the Agent Group should terminate unexpectedly, it is restarted and reads the state of the group members from persistent storage. The Agent Group's restart is transparent to the Agents. They actually communicate with an Agent Group Proxy (instead of an Agent Group), which shields them from Agent Group failures.

Figure 11 illustrates the flow of a typical collaborating Mobile Agent. Each Agent creates an Agent Group Proxy for each Agent group it wishes to join. The proxy's primary responsibility is to maintain an active connection to its associated Agent Group and to reestablish the connection or re-create the Agent Group, as needed, during Agent Group failures.

When the Agent Group Proxy is initialized, it establishes a connection with the appropriate Agent Group. It first attempts to find a reference to it in the name space. If this fails, it creates the Agent Group and enters a reference to it into the name space. The algorithm guarantees the atomicity of this operation.

After the proxy has created the Agent Group or established a connection to it, the Agent continues its computations and migrations. Eventually, it may attempt to collaborate its results. This is accomplished by means of the Agent Group Proxy. If the Agent Group has failed or is in a unknown state, the proxy will be unable to contact it. If this occurs, the Agent Group Proxy retries the communication. If, at this point, the proxy is still unable to communicate with the Agent Group, it recreates it and updates the name space with a reference to the new Agent Group. The re-creation of the Agent Group is serialized to prevent multiple Agent Group Proxies from simultaneously doing so. If a proxy determines that the Agent Group is in the process of being re-created, it simply waits until it can find a reference to the new group in the name space. Once the Agent Group has been re-created, the proxy retries the collaboration.

As mentioned earlier, Agent Groups provide a distributed events mechanism in addition to the synchronous collaboration framework. The distributed events mechanism enables the Agent Group to notify members of the group of outstanding events, such as the termination of an Agent, or the detection of a collaboration deadlock. Agents may build on this mechanism to torward application-generated events to other members in the group Hence, if an Agent catches an application-generated exception it may notify the other Agents in the group before terminating. Figure 10 illustrates how the Agent Group forwards an Exception Event, generated by one of its Agents, to the rest to the group.

Currently, the Agent Group handles distributed events by maintaining a (possibly remote) reference to an event queue associated with each Agent. The Agent Group forwards all events it receives to the other members of the group by enqueuing it. The Agent Group may be implemented without a remote referencing capability, but this would add significant complexity. In the current implementation, each Agent contains an events thread which is responsible for dequeuing the event and calling the application-specific event handler. (This thread could easily be a process, if threads were not available.)

In addition to forwarding events to members of the group, the Agent Group may generate its own events and distribute those to the group members. As an example, the Agent Group distributes a Deadle & Event to the group members when its detects a deadlock situation, as illustrated in Figure 9.

As mentioned earlier, Agent Groups track the migrations of their constituent Agents, with help from the Conduit Server (in the current implementation). If an Agent is in transit when the Agent Group is forwarding events, it queues the events locally, as shown in Figure 10. Once the Agent arrives at its destination, it notifies the Agent Group, via the Conduit Server. The Agent Group then flushes the events it stored locally for that Agent.

Agent Groups implement varying levels of persistence, as defined by the actual configuration. Memberships and Agent states are updated infrequently, so they are generally written to persistent storage. However, local queues maintained on behalf of intransit Agents may also be saved in persistent storage, if desired.

Implementation of the Agent Group in an object oriented language enables applications to extend its functionality, if required, by subclassing the Agent Group object.

### 5. Benefits of the Invention

The work described above provides several benefits. It greatly simplifies the implementation of synchronous collaborating Mobile Agents, especially for applications that subdivide a complex task into a series of related sub-tasks. There is no need for application developers to learn knowledge query representation languages, such as KQML, or to develop complex Ontologies. The dynamic synchronous collaboration framework provides a natural programmatic implementation that may be programmed in a

number of languages. An added benefit of this scheme is that collaboration is implemented as part of the application, programmed in the same language as the rest of the application. The current implementation in an object-oriented language (Java) also enables the technology to be easily extended so that more complex intelligence schemes may be supported.

Agent Groups facilitate Mobile Agent tracking and may also be queried by tools that monitor Agents. In addition, collaboration may be performed through discovery, as with many knowledge representation languages.

Agent Groups also offer reliability by providing persistent Agent Group membership and Agent state information. Furthermore, Agent Group Proxies shield Agents from the effects of Agent Group failures. They detect an Agent Group's failure and automatically restart the failed Agent Group (which then restores the state of its membership from persistent storage) and retry the current operation (e.g., collaboration). The algorithm also guarantees the atomicity of Agent Group creation and re-creation.

An Agent Group also detects Agent failures and deadlocks and forwards this information to the other members of the group via its distributed events mechanism. Furthermore, this mechanism allows Mobile Agents to asynchronously notity associated Agents of relevant events, such as the catching of an exception.

Implementation of Agent Groups in an object-oriented language also enables additional application-specific functionality to be easily added via inheritance and polymorphism.

# Design Specification for Java Agent Coordination

Version 0.2<sup>1</sup>

## 1. Introduction

Java agents have the capability of coordinating their activities. This coordination takes two main forms, synchronized collaboration and asynchronous notifications. These modes of communication complement each other and their implementations are related.

### Collaboration

The collaboration paradigm is implemented as follows

- multiple agents perform computations at different nodes in the network;
- after performing all or a subset of their operations, agents want at a distributed synchronization point until all agents have "arrived";
- agents coordinate by potentially serialized execution of a synchronized method.

Coordination can take the form of performing computations on intermediate results and/or updating agent inneraries.

### Notification

The notification scheme uses a distributed events mechanism to communicate agent state changes that occur asynchronously. It is mainly utilized for distributed exception handling, but may also be used to notify related agents of events, such as another's termination.

As described above, agent coordination utilizes distributed synchronization and event handling. However, Java possesses neither of these. Actually, its synchronization primitives are limited to cortical sections on a single system and a notification scheme that can only handle a single type of event. Hence, a great deal of the complexity in the task of agent coordination is comprised of implementing mechanisms to overcome Java's unsuitability for distributed processing. These mechanisms are described in the remainder of this document, along with the new objects that implement them

## 2. Synchronization

As mentioned above, agent coordination requires distributed synchronization mechanisms, such as locks and events. Since Java does not provide any distributed locking, we are faced with the following choice:

- 1. Unlize a centralized locking scheme.
- Develop our own distributed locking paradigms
- Use Java's native methods to interface with the operating system's synchronization primitives.

The latter choice is unacceptable because it compromises the portability of our agent intrastructure, whereas the first option may potentially introduce considerable network overhead. The second alternative also requires significant development effort even to implement a well-known solution to the problem

In the interest of expediency (as required by the tightness of our schedule), the initial Java agent intrastructure utilizes RMI to implement a centralized locking scheme. Locking is implemented via method invocations on a potentially remote object. (called an *AgentGroup*. See Section 3 for details.) Agent coordination is implemented by (remote) invocations on a method which requires synchronized access. (See Section 3.)

## 3. CollaboratorAgent and AgentGroup

Agents that may wish to collaborate their results subclass CollaboratorAgent, an abstract class derived from Agent—CollaboratorAgent contains a minimum of two threads – one to perform computation and to travel and another to handle asynchronous event notifications. Applications that contain collaborating agents subclass CollaboratorAgent and, of course, these derived classes may implement several computation threads

Each collaborating agent belongs to one or more agent groups, which are described by Agent Group objects. Agent Group is actually a distributed RMI object. AgentGroup defines the interface, AgentGroupImpl, an abstract base class derived from PersistentEventGroupImpl, provides the implementation. (See Design Specification for Destributed Java Events for a description of PersistentEventGroupImpl.)

An AgentGroup is essentially a unit of coordination. Hence agents may coordinate with all the other agents in an AgentGroup. They may also create new AgentGroups on demand, and join and leave groups at will. (In practice, AgentGroup must be subclassed to implement agent collaboration. However, this document does not distinguish between the base class and its derived classes and refers to them collectively as AgentGroups.)

An AgentGroup is an object that is essentially shared among the members of an agent coordination group. It is owned by the Agent that initially creates the group (an agent group is created by instantiating AgentGroup) and accessed via a potentially remote RMI reference.

The relationship between Collaborator Agent and Agent Group is similar to that of Thread and Thread Group. A Thread Group maintains references to the Threads composing the group; an Agent Group maintains a similar list of its Collaborator Agents. Both Thread Groups and Agent Groups form a hierarchy and each contains a reference to its parent group. Thread's constructors are either passed a reference to a Thread Group or they save a

reference to the parent's Thread's group. Likewise, CollaboratorAgent's constructors may be passed one or more AgentGroups or save a reference to AgentGroup of its parent, if it exists.

However, there is one noticeable difference between the two types of groups. A Thread may only belong to one ThreadGroup at a time, whereas a CollaboratorAgent may simultaneously be a member of several AgentGroups, which constitute a hierarchy. Hence, Threads contain a reference to their associated. ThreadGroup, but CollaboratorAgents maintain a list of references to their AgentGroups.

Support for multiple AgentGroups facilitates coordination among related groups of agents and also enables the creation of an AgentGroup hierarchy through which communication may be propagated. The pilot application may utilize multiple agent groups, as shown in Figure 1.

This figure portrays an example of two AgentGroups. AgentGroup A consists of three agents – one on each LAN in the system, whereas AgentGroup B contains agents on multiple nodes on LAN 3. A distributed application running on a configuration such as this typically creates multiple AgentGroups when it needs to traverse the WAN. In this case, 3 agents are created in AgentGroup A, one for each LAN. Once they arrive on a node, these agents clone themselves, creating more agents to be distributed across nodes on the LAN (e.g., AgentGroup B). This approach minimizes network traffic over the WAN and forms a multi-level hierarchy of AgentGroups. Agents in the intra-LAN groups (e.g., AgentGroup B) can communicate their results, which can then be coordinated with the inter-LAN group (i.e., AgentGroup A).

Java Agent Collaboration/Exception Handling (11/12/96)

By default, RMI passes all local objects by copy. However, the above scheme requires that each Agent actually maintain (remote) references to its AgentGroups. Hence, the agent infrastructure overrides some of RMI's object serialization methods to generate the required references.

## 4. Notifications and Exceptions

Both asynchronous notification and collaboration are implemented via the associated AgentGroup object. The following description serves as an example of asynchronous notification handling via distributed events. (See *Desten Specification for Distributed Java Events* for more details on event handling.)

- 1. An agent catches an exception and wishes to notify the other members of the group.
- 2 The agent posts an AgentLaceptionEvent to the AgentGroup via the group's postEvent method. The AgentExceptionEvent indicates the type of exception that occurred.
- 3 The AgentGroup posts the Agenth/sceptionf/yent to the other agents in the group
- 4 Each agent's Event Handler performs application-specific handling of the ExceptionEvent

If the agent that caught the exception wishes to notify another associated Agent Group, it repeats the above procedure with the next AgentGroup object.

Occasionally, the Agent Group may generate events that it directly forwards to a member of the group (e.g., to "ping" it after it tails to arrive at a collaboration point) or others that it "multicasts" to its members (e.g., an Agent's failure to reply to a ping)

### 5. Collaboration

Agent collaboration is more complicated than asynchronous notifications. It is implemented as follows:

- 1. An agent performs some computation and arrives at a synchronization point
- The agent performs a (remote) invocation of the AgentGroup's collaborate method, passing it an AgentStatus object.
- If no collaboration is in-progress (i.e., this is the first agent that has requested collaboration), collaborate calls its synchronized beginCollaborate method, which initializes the number of agents to wait for before collaboration may begin (i.e., n-1 for an n-agent group). (Race conditions are handled by checking if the agent count has been initialized (i.e., ic is non-zero) before continuing. A race implies that two agents are attempting to initiate the same collaboration. Otherwise the application is semantically incorrect.) This routine saves the requesting agent's unique ID (obtained from the AgentStatus object) and starts a collaboration timer (with sufficient time for agents to arrive across the WAN) by passing a configurable time-out value to the AgentGroup's wait method.
- Otherwise (i.e., if a collaboration is in-progress), collaborate calls the synchronized decrementCollaborate method to add the requesting agent's unique ID to the list of

WO 98/21662 PCT/US97/20232

### \_176-

### Mitsubishi Electric ITA Confidential

agents arriving at the collaboration point and to decrement the waiting agent counter. If the counter is non-zero, this method blocks with no time-out value. Otherwise, the Agent Group awakens the other threads waiting for collaboration to commence.

- 5. If the timer expires, all agents did not arrive at the collaboration point in time. This may occur because an agent received an uncaught exception and terminated unexpectedly or because a deadlock condition exists. (Since agents may belong to multiple groups, overlapping collaborations could result in deadlock. However, a properly coded application will not generate deadlocks because the collaboration points must be known a priori and must be executed in the same order among collaborating agents, i.e., collaboration must first handled at the leaf Agent Group and propagated up the hierarchy.) If a time-out occurs, the Agent Group thread miniating the collaboration (on behalf of its associated CollaboratorAgent) is awakened and performs the following:
  - It calls the AgentGroup's checkCollaborate method which returns the collaboration state (either CollaborationSucceeded or CollaborationFailed, depending on the value of the waiting agent count)
  - If the collaboration tailed, the collaborate method calls recoverCollaborate. This method attempts to communicate with the agents that did not arrive at the collaboration point by "pinging" them (It determines these agents by comparing the list of arrived agents with the group membership.) The ping is actually performed via a message to the Conduit Server on the node where each agent was last known to be executing. If the agents are located and any of them is in the Collaborate state and but has not arrived at this collaboration point, a collaboration deadlock has occurred and the collaboration state is set to CollaborationFailed. Otherwise, it is set to CollaborationRetry and the Agent Group thread retries the collaboration up to a configurable number of times (after which the state will be set to CollaborationFailed if the collaboration still times out.)
  - The mitiating Agent Group thread wakes up the other blocked threads by calling notifyall on the AgentGroup.
- 6. Once all the collaborating Agent Group threads have been awakened, tenther because the counter has dropped to 0 or a time-out occurred), they call the AgentGroup's checkCollaborate method. It this method returns a state other the CollaborationSucceeded, each thread returns the appropriate exception (i.e., either CollaborationFailedException or CollaborationDeadlockException) to its invoking CollaboratorAgent.
- 7. If the collaboration state is CollaborationSucceeded, collaboration commences by executing a potentially synchronized application-specific method, analyzeResults, to perform the collaboration, analyzeResults is an abstract AgentGroup method that must be implemented by derived classes to perform application-specific collaboration. As a result of collaboration, agent itingrances may be updated.
- As each thread completes its collaboration, it replies to the remote collaborate invocation, passing any state specified by the implementation, (e.g., updated itmeraries).
- The agents then continue execution on their current node and travel as required by their itineraries.

# Design Specification for Distributed Java Events

Version 0.21

#### 1. Introduction

This document describes a general-purpose solution to distributed event management

## 2. Overview

This section provides a high-level description of the objects that implement the distributed events framework.

#### 2.1. Objects

#### Events

Events are described by classes that derive from *EventType*—Each EventType object includes: a unique ID (a String) generated by the constructors and a description of the event (a String) optionally passed to the constructors.

#### Event Handler

The EventHandler interface specifies the handleEven() method which implements an Event Handler—bach application must provide its own Event Handler to perform application-specific event management.

#### **Event Notification**

The EventPost interface specifies the postEvent() method which implements event noufication. Several of the classes described below implement this interface.

#### Event Gueso

Any object receiving nonfication of events must own an Event Queue and an associated thread that manages the queue. The Event Queue's constructor is passed an EventHandler stub. It instantiates an EventQueueThread (a projected class derived from Thread) to manage the queue and passes the EventHandler stub to its constructor. The EventQueueThread's run() method removes events from the queue and calls the handlelivent() method.

69/26/96 Version 0.1 Initial revision.

11/12/96 Version 0.2 Expanded discussion of Event Manager and Event Group Added Reliability Features and Garbage Collection sections.

<sup>1</sup> Revision History:

An Event Queue is a distributed RMI object. EventQueueImpl implements the EventPost interface by appending the specified EventType object to the queue and calling the associated EventQueueThread's notify() method. This action wakes up the EventQueueThread (if it was blocked). The thread then proceeds to dequeue each pending event and pass it to the handleEvent() method.

#### **Event Manager**

The Event Manager handles the registration, posting, and notification of events. When objects request notification of specific event types, they must pass the Event Manager a reference to their EventPost interface. The Event Manager saves the reference in a hash table that it uses to map event types to their notification requests. When an object posts an event (via the Event Manager's postEvent() method), the Event Manager obtains the list of objects to notify from the hash table and calls each of their postEvent() methods.

The Event Manager also maintains a fist of objects that have requested notification of all events. Whenever it receives an event, the Event Manager also forwards it to these objects, by calling each of their postEvent() methods.

EventManager is an RMI distributed object. EventManager describes the interface, whereas EventManagerImpl provides the implementation. EventManager defines methods to manage event registrations (e.g., add and delete registrations).

EventManagerImpl also implements the EventPost interface—Its postEvent() method is passed an event from its originator and notifies the recipients of the event by invoking their postEvent() methods.

At most one Event Manager runs on each node in the Agent system. A reference to it can be obtained via the RMI Registry

#### **Event Group**

A group of objects interested in a common set of notifications may form an Event Group EventGroup is a distributed RMI object: EventGroup defines the interface, EventGroupImpl consists of the implementation. EventGroup defines methods that manage the group (e.g., add and remove members)

Whereas the Event Manager filters posted events on behalf of its clients, forwarding them only the events they requested, the Event Group performs no filtering. EventGroupImpl implements the EventPost interface. However, its postEvent() method forwards each event it receives to every member of the group (by calling their postEvent() methods).

to practice, twent Groups should be used sparingly because they could allow an abusive application to generate unwanted nonfications. The Agent framework does utilize this mechanism, but it verifies that all events are generated by a group member and it only utilizes the Event Group for some well-known events, such as the termination of an Agent.

Each Event Group is identified by a unique name either passed to its constructor or assigned by it. Objects may obtain a handle to a particular Event Group by presenting the RMI registry with this unique name.

## 2.2. Reliability Features

The Distributed Events framework incorporates several reliability features. These generally take the form of persistent state and proxy objects.

#### **Event Manager**

The Distributed Events framework shields objects from the effects of Event Manager failures in two ways:

- · by saving its state (i.e., event registrations) to persistent storage, and
- · by encapsulating its functionality in a proxy object.

The Event Manager saves the following items in the persistent store:

- the hash table mapping specific event types to the objects registered to receive them and
- the list of objects to be notified of all events

Each time an object either registers or "unregisters" its interest in receiving any (or all) events, the Event Manger writes the updated event registrations (i.e., either the hash table or the list of objects, but not both) to persistent storage via the Persistent Storage Manager. These are fairly intrequent operations, so the performance unpact of this process should be negligible. (See Design Specification for Java Agent Persistence Package for details on the Persistent Store Manager.)

Whenever the Event Manager is started, its unmalization code attempts to recover any existing event registrations from persistent storage. Hence, registrations are not lost when the Event Manager fails.

In addition, the Event Manager Proxy also prevents Objects from experiencing the effects of Event Manager failures. It acts as a wrapper object for the Event Manager. Each Object wishing to communicate with the Event Manager must first create an *EventManagerProxy* object. The proxy obtains a reference to the Event Manager via the RMI Registry. If, at any point, the proxy is unable to communicate with the Event Manager, it will attempt to obtain a new reference from the registry. It will retry this operation several times before throwing an exception.

Furthermore, if the Event Manager should tail, it will automatically be re-started by the Java Agent System.

### Persistent Event Group

The Distributed Events traineweak provides a general-purpose implementation of Event Groups (i.e., EventGroup), as described above. However a also provides a reliable implementation of Event Groups. Persistent Event Groups. Persistent Event Group is a distributed RMI object that extends EventGroup—the interface is defined by PersistentEventGroup and the implementation is provided by PersistentEventGroupImpl, a subclass of EventGroup impl. Persistent Event Group artizes persistent storage in much the same manner as the Event Manager. Whenever an Object joins or leaves the group, it saves a reference to it in persistent storage.

Each Persistent Event Group is also encapsulated in a proxy object: PersistentEventGroupProxy. This proxy operates somewhat differently than the Event Manager Proxy, depending on how it is constructed. In some cases, it will attempt to locate a named Persistent Event Group in the RMI registry. If a name is not supplied to the constructor, it will create a new Persistent Event Group and register it.

Distributed Java Events (11/12/96)

PNSDOCID: -MO GROSSOM ! .

Since Event Groups are temporary objects, unlike the Event Manager, which is a persistent server, their proxies cannot expect their associated Persistent Event Groups to be automatically re-started upon failure. Hence, a proxy may re-create the group if it is unable to obtain a reference to it after sufficient retries.

This, however, introduces a race condition wherein multiple proxy objects may simultaneously attempt to re-create the Persistent Event Group. This is handled by the following mechanism:

- If the owner of the Persistent Event Group detects the failure, it re-creates
  the group. (The owner is defined as the proxy that initially created the
  group.)
- If the owner does not detect the failure in a configurable length of time, other proxies may attempt to re-create it.
- The Persistent Event Group is re-created via the following steps:
  - Attempt to create a temporary binding in the RMI name space with a well-known name derived from the Persistent Event Group's unique name.
  - If the binding does not return an Already Bound Exception, proceed to re-create the Persistent Event Group and then remove the temporary binding (Otherwise, another proxy is re-creating it. So want for its completion.)

## 2.3. Garbage Collection

Both the Event Manager and Event Group objects must be prepared to garbage collect state references. This is simply performed by deleting any objects (i.e., EventPost stubs) that it cannot communicate with. Hence their postEvent() methods handle garbage collection after notifying all interested objects of the event.

## 3. Changes to Agent Implementation

### CollaboratorAgent

The CollaboratorAgent class contains a reference to an event queue (i.e., an Eventi, amount object), which is instantiated by its constructors

The Event Queue does not persist across an Agent's travels. Hence, its *prepareForTransit()* method flushes the queue and voids the Agent's reference to the queue before it travels. Its associated Agent Groups save any events that occur while the Agent is in-transit. The *completedTransport()* method, called after the Agent arrives at its destination, constitutes a new EventQueueImpl object and thishey any events saved by the associated Agent Groups while the Agent was in-transit.

#### AgentStatus

The AgentStatus class contains a reference to the EventPost interface implemented by the CollaboratorAgent's Event Queue. It also contains an Agent's unique ID and current status. Hence, it will serve as both an Event Queue and a status indicator.

Distributed Java Events (11/12/96)

#### AgentGroupImpl

The AgentGroupImpl class derives from PersistentliventGroupImpl. Thus, it not only enables Agent collaboration, but also provides reliable group event handling

As a result, Agent Groups may implement different levels of persistence: Group membership is always written to persistent storage, but queued events for in-transit agents will also be saved if the Agent Group's configuration allows it

Occasionally, the Agent Group may generate events that it directly forwards to a member of the group (e.g., to "ping" it after it fails to arrive at a collaboration point) or others that it "multicasts" to its members (e.g., an Agent's failure to reply to a ping). Group members may also broadcast an event to the group (e.g., an Agent may inform the group that it has encountered an exceptional condition)

## AgentEvent

The AgentEvent class is the superclass of all events generated by Agents. It includes the Agent's unique ID.

• Each gueue has an associated EventQueueThread started by the constructor.
• The thread degretors events and calls their handlers.

S
10/14/96 6:55p Noemi

    Base class for distributed events. EventType describes an event.
    It contains: a unique ID (generated by the EventManager) and a description.
    (optionally passed to the constructors).

                                                                                          ELECTRIC ITA

## CLAIMS

What is claimed is:

5

10

15

20

25

30

35

1. In a computer network including at least a first computer and a second computer, an apparatus for performing a task in a second computer, comprising:

a routine that generates a mobile agent object in the first computer, the mobile agent including both data and executable code;

a protocol for transmission of the mobile agent from the first computer to the second computer, wherein execution of the mobile agent in the second computer following such transmission prompts the task to be performed in the second computer; and

an itinerary containing a reference to each destination computer to which the mobile agent is designated to migrate and a reference to a method associated with each respective destination computer reference, the respective method being invoked when the mobile agent is present on the respective destination computer.

- 2. The apparatus of claim 1 wherein the transmission protocol includes a routine in the first computer for serializing the mobile agent to generate a stream of data therefrom.
- 3. The apparatus of claim 2 wherein the transmission protocol includes a routine in the second computer for deserializing the stream of bytes to regenerate the mobile agent therefrom.
- 4. The apparatus of claim 1 wherein the task is data gathering, and wherein the mobile agent is transmitted back to the first computer from the second computer following completion of such data gathering.
- 5. The apparatus of claim 1 wherein the mobile agent

-265-

migrates to a plurality of destination computers within the computer network.

6. The apparatus of claim 1 wherein at least one destination computer reference is a Uniform Resource Locator.

- 7. The apparatus of claim 1 wherein at least a portion of the executable code required for invoking the method is retrieved from a mobile codebase portion of the executable code included in the mobile agent.
- 8. The apparatus of claim 7 wherein the mobile agent includes a reference to a home codebase located on the first computer, the reference being employed to retrieve required executable code which is not present in the mobile codebase.
- 9. The apparatus of claim 8 wherein required executable code is sought first in the computer on which the mobile agent is executing, then in the mobile codebase, and finally on the home codebase.
- 10. The apparatus of claim 8 wherein a new thread is formed for execution of the mobile agent in the destination computer following receipt of the mobile agent, and wherein a security feature prevents the mobile agent from operating outside a scope assigned to such thread.
- 11. The apparatus of claim 8 wherein the mobile agent further includes sub-objects.
- 12. The apparatus of claim 1 wherein a persistent local copy of the mobile agent is stored following receipt of the mobile agent, and wherein such copy is overwritten with an updated persistent copy following agent execution.

13. In a computer network including at least a first computer and a second computer, a method for performing a task in a second computer, comprising the steps of:

generating a mobile agent object in the first computer, the mobile agent including both data and executable code;

transmitting the mobile agent from the first computer to the second computer;

receiving the mobile agent in the second computer; and executing the mobile agent in the second computer in accordance with an itinerary which contains a reference to each destination computer to which the mobile agent is designated to migrate and a reference to a method associated with each respective destination computer reference, the method associated with the second computer being invoked when the mobile agent is present on the second computer.

- 14. The method of claim 13 including the further step of serializing the mobile agent to generate a stream of data therefrom in the first computer.
- 15. The method of claim 14 including the further step of deserializing the stream of bytes to regenerate the mobile agent therefrom in the second computer.
- 16. The method of claim 13 wherein the task is data gathering, and including the further step of transmitting the mobile agent back to the first computer from the second computer following completion of such data gathering.
- 17. The method of claim 13 including the further step of causing the mobile agent to sequentially migrate to a plurality of destination computers within the computer network.
- 18. The method of claim 13 including the further step of employing a Uniform Resource Locator as one of the at least one destination computer reference.

5

10

15

20

25

- 267 -

19. The method of claim 13 including the further step of retrieving at least a portion of the executable code required for invoking the method from a mobile codebase portion of the executable code included in the mobile agent.

5

20. The method of claim 19 wherein the mobile agent includes a reference to a home codebase located on the first computer, and including the further step of employing the reference to retrieve required executable code which is not present in the mobile codebase.

10

21. The method of claim 20 including the further step of searching for required executable code first in the computer on which the mobile agent is executing, then in the mobile codebase, and finally on the home codebase.

15

22. The method of claim 21 including the further step of forming a new thread in the destination computer for execution of the mobile agent following receipt thereof, and wherein a security feature prevents the mobile agent from operating outside a scope assigned to such thread.

20

23. The method of claim 21 including the further step of inserting sub-objects into the mobile agent.

25

24. The method of claim 13 including the further step of storing a persistent local copy of the mobile agent following receipt thereof, and overwriting such copy with an updated persistent copy following agent execution.

30

25. In a computer network including at least a first computer and a second computer, an apparatus for performing a task in a second computer, comprising:

a routine that generates a mobile agent object in the

35

first computer, the mobile agent including both data and executable code;

a protocol for transmission of the mobile agent from the first computer to the second computer, wherein execution of

5

10

15

the mobile agent in the second computer following such transmission prompts the task to be performed in the second computer, at least a portion of the executable code required for execution being retrieved from a mobile codebase portion of the executable code included in the mobile agent; and

a reference to a home codebase located on the first computer, the reference being employed to retrieve required executable code which is not present in the mobile codebase.

- 26. The apparatus of claim 25 wherein the transmission protocol includes a routine in the first computer for serializing the mobile agent to generate a stream of data therefrom.
- 27. The apparatus of claim 26 wherein the transmission protocol includes a routine in the second computer for deserializing the stream of bytes to regenerate the mobile agent therefrom.
- 28. The apparatus of claim 25 wherein the task is data gathering, and wherein the mobile agent is transmitted back to the first computer from the second computer following completion of such data gathering.
  - 29. The apparatus of claim 25 wherein the mobile agent migrates to a plurality of destination computers within the computer network.
- 30. The apparatus of claim 29 wherein the mobile agent further includes an itinerary containing a reference to each destination computer to which the agent is designated to migrate and a reference to a method associated with each respective destination computer reference, the respective method being invoked when the mobile agent is present on the respective destination computer.
  - 31. The apparatus of claim 30 wherein at least one destination computer reference is a Uniform Resource Locator.

-269 -

32. The apparatus of claim 25 wherein required executable code is sought first in the computer on which the mobile agent is executing, then in the mobile codebase, and finally on the home codebase.

- 33. The apparatus of claim 25 wherein a new thread is formed for execution of the mobile agent in the destination computer following receipt of the mobile agent, and wherein a security feature prevents the mobile agent from operating outside a scope assigned to such thread.
- 34. The apparatus of claim 25 wherein the mobile agent further includes sub-objects.
- 35. The apparatus of claim 30 wherein a persistent local copy of the mobile agent is stored following receipt of the mobile agent, and wherein such copy is overwritten with an updated persistent copy following agent execution.
- 36. In a computer network including at least a first computer and a second computer, a method for performing a task in a second computer, comprising the steps of:

generating a mobile agent object in the first computer, the mobile agent including both data and executable code;

transmitting the mobile agent from the first computer to the second computer;

receiving the mobile agent in the second computer;

retrieving at least a portion of the executable code required for invoking the method from a mobile codebase portion of the executable code included in the mobile agent;

employing a reference to a home codebase located on the first computer to retrieve required executable code which is not present in the mobile codebase; and

executing the mobile agent in the second computer such that the mobile agent prompts the task to be performed in the second computer.

37. The method of claim 36 including the further step of serializing the mobile agent to generate a stream of data therefrom in the first computer.

- 38. The method of claim 37 including the further step of deserializing the stream of bytes to regenerate the mobile agent therefrom in the second computer.
- 39. The method of claim 36 wherein the task is data gathering, and including the further step of transmitting the mobile agent back to the first computer from the second computer following completion of such data gathering.
- 40. The method of claim 36 including the further step of causing the mobile agent to sequentially migrate to a plurality of destination computers within the computer network.
- 41. The method of claim 40 wherein the mobile agent further includes an itinerary which contains a reference to each destination computer to which the agent is designated to migrate and a reference to a method associated with each respective destination computer reference, and including the further step of invoking the method associated with the respective destination computer when the mobile agent is present on the respective destination computer.
- 42. The method of claim 41 including the further step of employing a Uniform Resource Locator as one of the at least one destination computer reference.
- 43. The method of claim 36 including the further step of searching for required executable code first in the computer on which the mobile agent is executing, then in the mobile codebase, and finally on the home codebase.
- 44. The method of claim 36 including the further step of forming a new thread in the destination computer for
